#### Abstract

The infrared and Raman spectra of potassium trans-4-hexenoate (PT4H) have been measured in the crystalline state and in aqueous solution. Normal coordinate calculations have been carried out to explain the vibrational spectra. For crystalline PT4H it is concluded from the vibrational spectra in the $700-100 \mathrm{~cm}^{-1}$ region that the trans-skew (TS) and trans-cis (TC) forms coexist at 300 K and the TS form is stabilized at 100 K . For the PT4H ions in aqueous solution the TS form was found to be predominantly stabilized on micellization. In particular, the Raman spectra of a PT4H- $\mathrm{H}_{2} \mathrm{O}$ solution in the $1700-700 \mathrm{~cm}^{-1}$ range were investigated at various concentrations, and it was found that the stabilization of the TS form is reflected in vibrational modes characteristic of the $-\mathrm{CH}=\mathrm{CH}$ - and $\mathrm{CH}_{2}$ groups. The difference Fourier-transform infrared (F.t.i.r.) spectra of PT4H- $\mathrm{H}_{2} \mathrm{O}$ (or PT4H- $\mathrm{D}_{2} \mathrm{O}$ ) solutions have also been measured at various concentrations. The infrared absorption spectra of water were successfully cancelled out in the 1500-900 $\mathrm{cm}^{-1}$ region for $\mathrm{H}_{2} \mathrm{O}$ and in the $1700-1300$ and $1000-700 \mathrm{~cm}^{-1}$ regions for $\mathrm{D}_{2} \mathrm{O}$. The concentration dependence of the difference F.t.i.r. spectrum was used to investigate conformational changes upon micellization.

Vibrational spectroscopy has been extensively used in studying the structural ordering of the saturated-hydrocarbon parts of fatty acids and their salts and phospholipids. In particular, Raman scattering has played an important role in conformational studies of surfactants. ${ }^{1-6}$ The effect of an unsaturated acyl chain on the physical properties of a phospholipid bilayer has been studied in relation to the functions of biological membranes. ${ }^{7-9}$ Raman scattering has also been used to study structural ordering and in carrying out conformational studies of bilayers and micelles having unsaturated chains. ${ }^{10-15}$

The utility of the vibrational spectrum in the $1200-1000 \mathrm{~cm}^{-1}$ region for investigating the conformation of unsaturated fatty acids has been pointed out by Lippert and Peticolas. ${ }^{10}$ Okabayashi et al. have shown from Raman studies in the $1200-200 \mathrm{~cm}^{-1}$ region that a specific rotational isomer of simple unsaturated surfactants is preferentially stabilized on aggregation. ${ }^{14.15}$

In recent years, Fourier transform infrared (F.t.i.r.) spectroscopy has permitted precise studies of molecular and conformational properties, and has made it possible to study aqueous micellar solution, ${ }^{16,17}$ multibilayer lipid membranes ${ }^{18-23}$ and monomolecular films. ${ }^{24}$

In the present work, Raman scattering and the F.t.i.r. technique have been used to investigate the conformational changes of simple unsaturated surfactants upon micellization.

## Experimental

## Materials

trans-4-Hexenoic acid was synthesized from crotyl bromide and dimethylmalonate, following the method of Eccot and Linstead ${ }^{25}$ (boiling point of trans-4-hexenoic acid, $106^{\circ} \mathrm{C}$ at $17 \mathrm{mmHg} \dagger$ ). Identification of the sample was made from ${ }^{1} \mathrm{H}$ and ${ }^{13} \mathrm{C}$ n.m.r. spectra. Potassium trans-4-hexenoate ( PT 4 H ) was prepared from the corresponding acid and potassium hydroxide in methanol and was recrystallized in the same solvent.

## Infrared Absorption Spectra Measurements

The infrared absorption spectra were recorded with a JASCO-DS-402G double-beam grating spectrometer in the $4000-400 \mathrm{~cm}^{-1}$ range and with a Hitachi FIS- 3 double-beam grating spectrometer in the $400-30 \mathrm{~cm}^{-1}$ region.

## Fourier-transform Infrared Spectra Measurements

Fourier-transform infrared (F.t.i.r.) spectra were measured with a Perkin-Elmer 1700 Fourier-transform infrared spectrometer. An attenuated total reflection (ATR) instrument ( ZnSe , sample volume $350 \mathrm{~mm}^{3}$ ) was used for measurements on the aqueous solutions.

## Raman Scattering Measurements

Raman spectra were measured with a JEOL model 400D Raman spectrometer. The 514.5 nm line of an argon-ion laser (NEC GLS-3200, 2W) was used as an excitation source.

## Normal-coordinate Treatment

A normal-coordinate analysis of the PT4H ion was made for possible rotational isomers; trans-skew (TS), trans-cis (TC), gauche-skew (GS), gauche'-skew (G'S) and gauche-cis (GC), the order going from the $\mathrm{CO}_{2}^{-}$group to the terminal group. The other isomers, which were omitted from the calculations, are expected to be much less stable owing to steric hindrance.

In the normal-coordinate calculations we assume that the infrared absorption bands increased in intensity on cooling, and the corresponding Raman bands arise from the TS form. This assumption is reasonable by reference to the infrared and Raman studies of potassium 5-hexenoate and potassium 4-pentenoate, ${ }^{15}$ Raman studies of various longchain unsaturated fatty acids ${ }^{26}$ and X-ray diffraction analysis of oleic acid. ${ }^{27}$

The Urey-Bradley-Shimanouchi force field (UBSFF) was used for calculations of normal mode frequencies. The calculations contain the force constants for (a) the cis$\mathrm{C} \cdots \mathrm{C}$ repulsion and (b) the interaction between $=\mathrm{CH}$ - out-of-plane wagging and $\mathrm{C}=\mathrm{C}$ torsional modes. Force constants of alkenes and potassium carboxylates were initially used, and those used in the molecular skeleton calculations were modified to obtain the best fit between the observed wavenumbers of the crystalline PT4H and those calculated ${ }^{\circ}$ by a least-squares method. The modified force constants (table 1) were used for calculations on other isomers.

A Melcom-Cosmo 700III/MP computer was used for all calculations by using the program NCTB prepared by Shimanouchi et al. ${ }^{28}$

${ }^{a}$ The units of the Urey-Bradley-Shimanouchi force constants
are mdyn $\AA^{-1}$ for stretching $(K)$, bending $(H)$, repulsion $(F)$, cis
repulsion $(R)$ and bond interaction $(P)$, and mdyn $\AA$ for out-of-
plane wagging $(W)$, torsion $(Y)$ ), the interaction constant $(W W)$
between the two neighbouring CH wagging modes, the in-
teraction constant $(W Y)$ between the CH wagging and $\mathrm{C}=\mathrm{C}$
torsional modes, and trans and gauche interactions (TC and
GC).

## Results and Discussion

In our previous paper ${ }^{15}$ we reported the vibrational spectra of two simple surfactants, potassium 4-pentenoate ( P 4 P ) and potassium 5 -hexenoate ( P 5 H ), and discussed the conformation of these molecules. From the vibrational spectra and the predictions of normal-coordinate calculations, it was shown that the skew form about the $\mathrm{C}-\mathrm{C}$ single bond adjoining the $\mathrm{C}=\mathrm{C}$ double bond is stabilized at low temperatures. This conclusion has been directly confirmed by the use of the skeletal deformation region in the vibrational spectra.

In the present paper, for potassium trans-4-hexenoate ( PT 4 H ) the temperature dependence of the vibrational spectra in the $1700-100 \mathrm{~cm}^{-1}$ region were investigated and normal-coordinate calculations were also made in order to explain the vibrational spectra (table 2). Results similar to those for P4P and P5H were obtained, i.e. the TS and TC forms also coexist in crystalline PT4H at room temperature ( 300 K ). The population of the TS form is much greater than that of the TC form at low temperature ( 100 K ),

[^1]since the intensities of the TC bands are extremely weak in both the infrared and Raman spectra. Thus the TS form is preferentially stabilized on cooling to 100 K , compared to the TC form, in the crystal.

The vibrational spectra in the $1700-700 \mathrm{~cm}^{-1}$ region are sensitive to the molecular conformation, as has been shown in our previous papers. ${ }^{14,15}$ Lippert and Peticolas ${ }^{2}$ pointed out the utility of this region in conformation studies of unsaturated fatty acids. However, little is known about the detailed vibrational state of simple unsaturated surfactants by analysing the vibrational spectra and assignments due to normalcoordinate calculations. To carry out more detailed conformational studies, a normalcoordinate analysis of simple surfactants in this region is required. Our discussion is mainly devoted to the utility of vibrational spectra in the $1700-700 \mathrm{~cm}^{-1}$ region in conformation studies of PT4H.

The stabilization of the TS form caused by cooling affects the infrared spectrum in the $1700-700 \mathrm{~cm}^{-1}$ region. The infrared band at $831 \mathrm{~cm}^{-1}$ observed at 300 K decreases in intensity on cooling, and the band at $1025 \mathrm{~cm}^{-1}$ disappears at 100 K . The other infrared bands increase in intensity at low temperatures. The 831 and $1025 \mathrm{~cm}^{-1}$ bands are due to the TC form. The population of TC is very small at 100 K since the intensities of these vibrational bands are extremely weak. Assignment of these two bands to the TC form is supported by the calculated results of the normal-coordinate analysis (table 2); the observed wavenumbers of 1025 and $831 \mathrm{~cm}^{-1}$ closely correspond to the calculated ones, 1019 and $834 \mathrm{~cm}^{-1}$, of the TC form. The wavenumbers of the other infrared bands and the corresponding Raman bands are in good agreement with the calculated ones of the TS form. Thus the vibrational bands of the crystalline PT4H in this region can be explained by the TS form, except for the above two bands.

For the vibrational modes characteristic of the - $\mathrm{CH}=\mathrm{CH}$ - group, the out-of-plane deformation mode is particularly useful for conformation studies, because it is predicted from calculations that the wavenumber of this mode is dependent on the molecular conformation.

The vibrational modes characteristic of $\alpha$ - and $\beta-\mathrm{CH}_{2}$ groups appear separately at the different wavenumbers, and are available for conformation studies.

## Conformational Change on Micellization: Raman Scattering Studies

A change in conformation of simple surfactants on micelle formation in aqueous solution can be directly confirmed by measurements of the concentration dependence of the Raman spectrum in the $700-100 \mathrm{~cm}^{-1}$ region. For instance, in the case of simple surfactants having a saturated hydrocarbon chain, it has been found that the intensity of the Raman band due to an accordion-like vibration of the all-trans form of the chain rapidly increases on micellization. ${ }^{6}$ This phenomenon is due to the predominant stabilization of the all-trans form in the micellar state. For simple surfactants having a $\mathrm{C}=\mathrm{C}$ double bond, the stabilization of a specific rotational isomer on micellization has also been confirmed by the Raman spectra in the skeletal deformation region. ${ }^{14,15}$

In the present paper the Raman spectrum of PT4H in $\mathrm{H}_{2} \mathrm{O}$ is dependent on concentration with regard to both the intensities and positions of the bands, as can be seen in fig. 1. The intensity of the $352-363 \mathrm{~cm}^{-1}$ band due to the TS form increases markedly with an increase in the concentration, while that of the $404 \mathrm{~cm}^{-1}$ band of the GS and G'S forms increases with dilution and broadening occurs [fig. 1(A)]. The ratio, $I_{352-363} / I_{404}$, increases rapidly with increasing concentration above $1.4-1.5 \mathrm{~mol} \mathrm{dm}^{-3}$, corresponding to the critical micelle concentration (c.m.c.). ${ }^{29}$ This observation shows directly the preferential stabilization of the TS form on micellization. Moreover, at lower concentrations the $620-624 \mathrm{~cm}^{-1}$ band intensity is greater than that of the $660-665$ $\mathrm{cm}^{-1}$ band, but it decreases at higher concentrations. This shows that the GC form is unstable at higher concentrations, compared to the GS and $\mathrm{G}^{\prime} \mathrm{S}$ forms.

Fig. 1. Raman scattering spectra of $\mathrm{PT} 4 \mathrm{H}-\mathrm{H}_{2} \mathrm{O}$ solutions $\left[(a) 0.33\right.$, (b) 1.3 and (c) $\left.4 \mathrm{~mol} \mathrm{dm}^{-3}\right]$ in the $700-200 \mathrm{~cm}^{-1}$ region (A) and the $1700-700 \mathrm{~cm}^{-1}$ region (B) at room temperature.

Fig. 2. Concentration dependence of the relative Raman peak heights ( $-I_{1209} / I_{1189} ; \mathrm{O}$, $I_{1020} / I_{1040}$ and $\left.\square, I_{856} / I_{885}\right)$ in the $1700-700 \mathrm{~cm}^{-1}$ region.

Such a conformational change also brings about a shift in the wavenumber of the Raman bands. Those at 479 and $352 \mathrm{~cm}^{-1}$ in a $4 \mathrm{~mol} \mathrm{dm}^{-3}$ aqueous solution are shifted to higher wavenumber as the concentration is lowered and reach 485 and $363 \mathrm{~cm}^{-1}$, respectively, at a concentration of $0.33 \mathrm{~mol} \mathrm{dm}^{-3}$. The wavenumber shift also shows a stabilization of the other rotational isomers at low concentrations, except for the TS form.

The Raman spectrum in the region of $1700-700 \mathrm{~cm}^{-1}$ is sensitive to changes in conformation upon micellization. Fig. 1(B) shows the Raman spectra of a PT4H- $\mathrm{H}_{2} \mathrm{O}$ solution at various concentrations. The Raman bands at 1454 and $1443 \mathrm{~cm}^{-1}$ are assigned to the scissoring modes of two methylene groups and the asymmetric deformation mode of the methyl group, respectively. From normal-coordinate analysis the $1454 \mathrm{~cm}^{-1}$ band is mainly due to the $\mathrm{CH}_{2}$ scissoring of the TS and TC forms, and the $1443 \mathrm{~cm}^{-1}$ band also has a contribution from the $\mathrm{CH}_{2}$ scissoring modes of other rotational isomers (GS, G'S and GC). The relative intensities of the two bands are dependent on the concentration. In the concentrated solutions ( $4 \mathrm{~mol} \mathrm{dm}^{-3}$ ) the intensity of the $1454 \mathrm{~cm}^{-1}$ band is larger than that of the $1443 \mathrm{~cm}^{-1}$ band. However, the 1443 $\mathrm{cm}^{-1}$ band increases in intensity with decreasing concentration. The intensity variation is due to the stabilization of TS or TC at higher concentrations.

In the $1330-1270 \mathrm{~cm}^{-1}$ region a broad and strong Raman band at $1309 \mathrm{~cm}^{-1}$ and a weak band at $1278 \mathrm{~cm}^{-1}$ are observed and are assigned to the in-plane deformation modes of the two $=\mathrm{CH}$ - groups. The intensity of the $1278 \mathrm{~cm}^{-1}$ band changes with concentration, as is seen in fig. 1 (B). The intensity of the band decreases and its position is shifted as the sample solution is diluted. Accordingly, the in-plane deformation mode is also sensitive to a change in conformation.

Four Raman bands at $1209,1020,977$ and $856 \mathrm{~cm}^{-1}$ observed in aqueous solution disappear in the crystalline state. From the normal-coordinate analysis assignments of these Raman bands were made as follows. The $1209 \mathrm{~cm}^{-1}$ band is assigned to the twisting mode of the $\mathrm{C}_{\beta} \mathrm{H}_{2}$ group adjacent to the $\mathrm{C}=\mathrm{C}$ double bond of the TC and GC forms or that of the $\mathrm{C}_{\alpha} \mathrm{H}_{2}$ group of the GC form. The $1020 \mathrm{~cm}^{-1}$ band arises from the symmetric stretching vibration of the $\mathrm{C}_{\alpha}-\mathrm{C}_{\beta}$ bond of the TC and GC forms. The band at $977 \mathrm{~cm}^{-1}$ is due to the rotational isomers, except for the TS and TC forms, and is assigned to the coupled vibrational mode between the $\mathrm{C}-\mathrm{CO}_{2}^{-}$stretching and $\mathrm{C}_{\beta} \mathrm{H}_{2}$

Fig. 3. The difference F.t.i.r. spectra of (A) PT4H- $\mathrm{H}_{2} \mathrm{O}[(a) 0.33$, (b) 0.64 , (c) 0.99 , (d) 1.32 , (e) 1.97 , (f) 2.63 and (g) $\left.3.3 \mathrm{~mol} \mathrm{dm}^{-3}\right]$ and (B) PT4H-D ${ }_{2} \mathrm{O}$ [(a) 0.33, (b) 0.66, (c) 0.99, (d) 1.32, (e) 1.97 and ( $f$ ) $2.63 \mathrm{~mol} \mathrm{dm}^{-3} \mathrm{~J}$.
rocking modes, and the $856 \mathrm{~cm}^{-1}$ band corresponds to the rocking vibration of the $\mathrm{C}_{\beta} \mathrm{H}_{2}$ group of the $\mathrm{G}^{\prime} \mathrm{S}$ and GC forms.

The relative peak heights, $I_{1209} / I_{184}, I_{1020} / I_{1040}$ and $I_{856} / I_{885}$, decrease markedly with increasing concentration, as is seen in fig. 2. A point of inflection in the plots of the relative heights vs. the inverse concentration corresponds to the critical micelle concentration of the PT4H ions. The existence of such an inflection shows that a conformational change occurs upon micelle formation.

In the region of $800-700 \mathrm{~cm}^{-1}$, a very weak, broad Raman band at $769 \mathrm{~cm}^{-1}$ and an extremely weak band at $710-715 \mathrm{~cm}^{-1}$ are observed, and are assigned to the out-of-plane deformation of the $=\mathrm{CH}$ - groups. The broadness of the $769 \mathrm{~cm}^{-1}$ band implies an overlapping of some bands, and it is difficult to discuss conformational changes using the

Raman bands in this region. However, the difference F.t.i.r. spectrum of the sample solution in this region is available for a study of conformational changes, as is discussed later.

## F.T.I.R. Absorption Studies

The difference F.t.i.r. absorption spectra were measured for the aqueous solutions of PT4H. In the region $1500-900 \mathrm{~cm}^{-1}$ the infrared absorption spectrum of the $\mathrm{H}_{2} \mathrm{O}$ molecule was successfully cancelled out.

Fig. 3(A) and (B) show the difference F.t.i.r. spectra of PT4H- $\mathrm{H}_{2} \mathrm{O}$ (or PT4H- $\mathrm{D}_{2} \mathrm{O}$ ) solutions at various concentrations. For concentrated solutions ( $3.3 \mathrm{~mol} \mathrm{dm}^{-3}$ ) the infrared band at $1236 \mathrm{~cm}^{-1}$ corresponded to the $1230 \mathrm{~cm}^{-1}$ bands in crystalline PT4H arising from the $\mathrm{C}_{\alpha} \mathrm{H}_{2}$ twisting vibrational mode of the TS form. The absorbance of the $1236 \mathrm{~cm}^{-1}$ band increases markedly with an increase in the concentration. At low concentrations a new band at $1263 \mathrm{~cm}^{-1}$ appears owing to the in-plane deformation mode of the two $=\mathrm{CH}$ - groups of the rotational isomers, except the TS form. The absorbance of the $1263 \mathrm{~cm}^{-1}$ band decreases rapidly with an increase in concentration, and finally this band becomes a very weak shoulder at a concentration of $3.3 \mathrm{~mol} \mathrm{dm}^{-3}$. These observations reveal that the TS form is preferentially stabilized in higher concentration.

The absorbance of these two bands is plotted as a function of the reciprocal of the concentration in fig. 4 . The absorbances of the 1236 and $1263 \mathrm{~cm}^{-1}$ bands change rapidly at a concentration of $1.4-1.5 \mathrm{~mol} \mathrm{dm}^{-3}$, and the curves do not follow the Beer-Lambert law. The inflections closely correspond to those in the plots of relative peak heights vs. $1 / C$ of the Raman spectra discussed in the present paper. The variation in absorbance is due to micelle formation.

The infrared absorption bands at 1315 and $1305 \mathrm{~cm}^{-1}$ are assigned to the coupled bands of the in-plane deformation modes of the two $=\mathrm{CH}$ - groups and the wagging vibration of the $\mathrm{C}_{\beta} \mathrm{H}_{2}$ methylene group coupled with the in-plane deformation of the $=\mathrm{C}_{\gamma} \mathrm{H}$ - group, respectively. For these two bands a dependence on concentration of the absorbance is also found.

Dilution of the $\mathrm{PT} 4 \mathrm{H}-\mathrm{H}_{2} \mathrm{O}$ solution results in an increase in the absorbance of the broad infrared band at $1020 \mathrm{~cm}^{-1}$. This observation corresponds to the concentration dependence of the Raman band intensity at $1020 \mathrm{~cm}^{-1}$ (fig. 1 and 2).

The position of the infrared band at $970 \mathrm{~cm}^{-1}$ is dependent on concentration, as is seen in fig. 3(A). The wavenumber shift is also caused by the preferential stabilization of the TS form.

When $\mathrm{D}_{2} \mathrm{O}$ was used as a solvent, the infrared absorption spectra of $\mathrm{D}_{2} \mathrm{O}$ in the region $100-700 \mathrm{~cm}^{-1}$ were successfully cancelled out. The difference F.t.i.r. absorption spectra of PT4H in $\mathrm{D}_{2} \mathrm{O}$ are found to be sensitive to changes in conformation, as is seen in fig. 3 (B). The coupled modes of the rocking vibrations of the $\alpha$ - and $\beta$-methylene groups appear in the region $870-800 \mathrm{~cm}^{-1}$. The infrared band at $808 \mathrm{~cm}^{-1}$, corresponding to the Raman band at $804 \mathrm{~cm}^{-1}$, is due to the rocking vibrational modes of the two methylene groups of the TS form, and the $841 \mathrm{~cm}^{-1}$ band is due to those of the TC and GS forms. The Raman band at $856 \mathrm{~cm}^{-1}$ arises from the $\mathrm{G}^{\prime} \mathrm{S}$ and GC forms.

In fig. 3(B) the absorbance of the $808 \mathrm{~cm}^{-1}$ band increases with increasing concentration, compared to that of the $841 \mathrm{~cm}^{-1}$ band. Such a variation occurs at concentrations near to the c.m.c. The infrared band at $855 \mathrm{~cm}^{-1}$ decreases in intensity with increasing concentration. This closely corresponds to the concentration dependence of the relative peak heights, $I_{856} / I_{885}$, in the Raman spectra of $\mathrm{PT} 4 \mathrm{H}-\mathrm{H}_{2} \mathrm{O}$ solutions discussed above.

For the region $800-700 \mathrm{~cm}^{-1}$ the five bands at $770,756,743,725$ and $715 \mathrm{~cm}^{-1}$, assigned to the out-of-plane deformation modes of the two $-\mathrm{CH}=$ groups for the five

Fig. 4. Concentration dependence of the infrared band intensity in the difference F.t.i.r. spectra of PT4H- $\mathrm{H}_{2} \mathrm{O}$ solutions ( $\mathrm{O}, 1263$ and $-1236 \mathrm{~cm}^{-1}$ ).
rotational isomers, are due to the GS, G'S, TS, GC and TC forms, respectively. The intensities of these bands seems to be dependent on concentration. The $743 \mathrm{~cm}^{-1}$ band arising from the TS form increases in intensity with increasing concentration. The infrared bands at 788 and $770 \mathrm{~cm}^{-1}$ become a very weak shoulder in higher concentration, showing the instability of the GS and G'S forms in the micellar state.

## Conclusions

Normal-coordinate analysis successfully explains the vibrational spectra of PT4H in the crystalline state and in aqueous solutions. In crystalline PT4H the TS and TC forms coexist at room temperature. However, the TS form is preferentially stabilized at lower temperatures.

In the micellar state of PT4H, the TS form is preferentially stabilized, compared to other rotational isomers. The stabilization of such a specific isomer causes an intensity change and wavenumber shift for a wide range of Raman spectra of aqueous solutions.

The difference F.ti.i.r. spectra of $\mathrm{PT} 4 \mathrm{H}-\mathrm{H}_{2} \mathrm{O}$ (or $\mathrm{PT} 4 \mathrm{H}-\mathrm{D}_{2} \mathrm{O}$ ) solutions are also available for the investigation of conformational changes. At a PT4H concentration $>0.3 \mathrm{~mol} \mathrm{dm}^{-3}$ the difference F.t.i.r. spectra of $\mathrm{H}_{2} \mathrm{O}$ or $\mathrm{D}_{2} \mathrm{O}$ are successfully cancelled out, and reproducible difference F.t.i.r. spectra are obtained. For simple surfactants having a higher c.m.c., the change in intensity of infrared bands below and above the c.m.c. can be easily observed. Moreover, the wavenumber shift accompanying conformational change can also be measured precisely.

We express our gratitude to the Toyoda Physical and Chemical Research Institute for financial support.
